(Received 22 December 2010; accepted 14 January 2011; published online 7 February 2011)

We investigate the possibility of interconduction band gain without global inversion by engineering the conduction band effective masses so that the upper lasing subband has an effective mass considerably smaller than the lower lasing subband that could not be obtained in conventional III-V materials. We recover the expected dispersive gain shape for similar masses and contrasting results if the effective masses characterizing the relevant subbands are very different. © 2011 American Institute of Physics. [doi:10.1063/1.3552204]

Intersubband (ISB) devices like the quantum cascade laser (QCL), in which the frequency of the emitted radiation is not limited by the semiconductor bandgap, can unleash the potential for many applications in the far infrared.¹ Midinfrared (MIR) QCLs already deliver high power at room temperature,² but at present the maximum operating temperature of a tetrahertz device is 186 K emitting at 3.9 THz.³ Conventional designs emitting at a given frequency hν have to have a maximum operating temperature T_max = ħν/k_B.⁴ The main difficulty at high temperatures is achieving population inversion and ISB lasing without inversion (LWI).⁵⁻⁷ may be a solution for this microscopic bottleneck. ISB LWI has been realized experimentally by exploiting the nonparabolicity of the conduction subbands and local population inversion near k=0 even though the lowest subband may have larger global occupation.⁵ Later on, valence-band-based designs have been proposed⁸ and more recently a mechanism combining band nonparabolicity with a k-space filtering in the TE mode of hole intervalence transitions in quantum wells has been introduced.⁹ However, holes thermalize very fast and it would be ideal to be able to exploit extreme nonparabolicity in the conduction bands. This can be achieved, e.g., in dilute nitride quantum wells.¹⁰⁻¹² ISB transitions in a similar dilute nitride system (InGaNAs-based) have been investigated both theoretically¹³,¹⁴ and experimentally.¹⁵ Previous simulations indicate a potential for both telecom Ref. 13 and MIR transitions in the (4 μm) ranges.¹⁴ Models such in Ref. 13 use phenomenological Lorentzian broadenings and can be used to fit experimental absorption but should not be applied for gain calculations. Among other limitations, they lead to strong unphysical absorption features below the gain. They further do not include relevant scattering mechanisms and many particle corrections that increase their relevance as the electronic density increases to reach the gain regime.¹⁶

In this paper we investigate the possibility of ISB gain without global inversion by engineering the conduction band effective masses using the NGF approach. The upper gain subband has an effective mass made considerably smaller than the lower lasing subband that could not be obtained in conventional III-V materials where the electron effective mass is proportional to energy gap. In this proof of concept we take a simple system—a single quantum well which nevertheless delivers gain at a relevant MIR wavelength (around 2 μm). The strong interaction between the N resonant states and the conduction band edge means that the conventional eight-band k·p method cannot be applied directly to GaAsN and related heterostructures. One must include the interaction between the N resonant states and the conduction band edge to describe the variation of the (zone-center) conduction band edge energy with N. This leads to a modified ten-band Hamiltonian as shown in Ref. 17. The ten-band Hamiltonian describes on average interaction of all N atoms with the host material. It has been observed that when N-related cluster states lie close in proximity, on energy scale, to the conduction band edge of the host material, the electron effective mass have even stronger increase with nitrogen concentration.¹⁸,¹⁹ This was explained by hybridization of the N-cluster states to Γ character of the host material conduction band.²⁰ Consequently we have modified the ten-band k·p Hamiltonian to describe the average interaction of the N, NN-pairs and other N-cluster states with the host material. To achieve this, the resonant N level (that on average describes all N-related states) is set at E_N = 1.35 eV. Coupling between those states and the Γ band edge (1.42 eV) of the host GaAs material is determined by the relations V_{NC} = 2.45/V where V is the nitrogen concentration. Other Hamiltonian matrix elements related to the GaAs host material are taken from standard literature.²¹ The absorption α(ω) or equivalently the gain spectra g(ω) = −α(ω) are evaluated within the context of a NGF approach. The susceptibility χ(ω) is directly related to the carriers Green’s functions G, which satisfies a Dyson equation,

$$\alpha(\omega) = \frac{4\pi\omega}{cn_b} \text{Im}\{\chi(\omega)\}, \quad \chi(\omega) = 2 \sum_{\mu,\nu} \varphi_{\mu,\nu}(k,\omega) .$$

(1)

Here n_b denotes the background refractive index, c is the speed of light, \(\varphi_{\mu,\nu}(k,\omega)\) is the transition dipole moment between the subbands \(\nu\) and \(\mu\), which are labeled as “−,” “+,” if belong to the lowest conduction band branch and “+,” if

belong to top conduction band (CB) branch [see Fig. 1(a)].
Thus in the discussion that follows, if electrons are injected in
the subband $e_{2+}$ and make a transition to subband $e_{3-}$,
creating a photon, this will be called a $e_{2+}$ to $e_{3-}$
transition. The numerical scheme used here can be summarized as fol-
low. The first step is the solution of the ten-band $k \cdot p$
Hamiltonian which includes the dilute nitrogen levels re-
sponsible for the extra nonparabolicity that gives rise to
strong differences in effective subband masses. The Green’s
functions and self-energies are expanded using eigenstates
and eigenvalues of this Hamiltonian. The model system ac-
cepted in this paper is globally out of equilibrium but the electrons are assumed to be thermalized within each
subband. For a feasibility study we control the total number
of electrons in each subband, which can in practice be
achieved, e.g., by optical pumping, selective doping or a
combination of both methods. Thus, the full NGF scheme is
simplified and reduces to the self-consistent evaluation of
chemical potentials and self-energy matrix elements which
lead to subband energy renormalization, dephasing constants,
and occupation functions. Finally, absorption and gain are
given by the solution of the integro-differential equation for
$\chi_{\mu}(k,\omega)$ obtained from the carriers Green’s function in lin-
ear response. The numerical matrix inversion technique
used to solve this equation is similar to the interband method
used in Ref. 25. The dephasing used in the numerical inver-
son is a frequency and momentum dependence approxima-
tion to the single-plasmon-pole dynamically screened
dephasing of Ref. 16 further simplified by a quasiparticle
approximation with thermal distributions. The proof of con-
cept structure chosen is a 7 nm Ga0.702Al0.298N0.02As/Al0.1Ga0.9As
QW. From the lowest to the upper subband, the effective
masses (at $k=0$, are given by $m_{1+}=0.125$, $m_{2+}=0.277$, $m_{3-}$
$=0.820$, $m_{4+}=2.119$, $m_{1-}=0.118$, $m_{2-}=0.109$, and $m_{3+$
$=0.088$. Those values are in good agreement with experi-
ments. Note that the energies are so nonparabolic
that the concept of effective mass does not make sense in the
whole Brillouin zone, but those values are useful to compare
the curvatures in the most relevant region of $k$-space, i.e.,
around $k=0$.
The nitrogen level has been positioned to create upper
bands ($e_{1+}-e_{3-}$) with lower masses that the lower states

$$e_{1+} - e_{3-}$$

FIG. 1. (Color online) Band structure (a) and corresponding occupation
functions (b) assuming that all subbands have an electronic density of
$n = 1.0 \times 10^{11}$ cm$^{-2}$ thermalized at 300 K. The convention is the same in both
panels. The dotted, dashed, and dot-dashed are, respectively, for the sub-
bands $e_{1+}$, $e_{2+}$, and $e_{3-}$. Local inversion in $k$-space is clearly seen.

$e_{2+}$ to $e_{1+}$

FIG. 2. (Color online) Corresponding band character $|\phi_{CB}\rangle$ (dots), nitrogen-
character $|\phi_{N}\rangle$ (dashed), and charge density $\Psi^2$ (solid) for $e_{2+}$ (top) and $e_{3-}$
(bottom).

$e_{2+}$ to $e_{1+}$

FIG. 3. (Color online) Gain without global population inversion. In the
dashed curve, the density for the $e_{2+}$, $e_{1+}$, and $e_{3-}$ subbands is the same,
$n_{up}=n_{low}=1.0 \times 10^{11}$ cm$^{-2}$. The curves below the dashed lines have a fixed
density in the $e_{2+}$ subband $n_{up}=1.0 \times 10^{11}$ cm$^{-2}$ and from top to bottom, the
(equal) density of subbands $e_{1+}$ and $e_{3-}$ increase by $n_{low}=1.1, 1.2, 1.3, 1.4 \times 10^{11}$. The curves above the dashed line do not have global LWI and are
here for a comparison. For those the (equal) $e_{1+}$ and $e_{3-}$ densities are fixed at
$n_{low}=1.0 \times 10^{11}$ cm$^{-2}$ and from bottom to top the density of the $e_{2+}$ subband
increases by $n_{up}=1.1, 1.2, 1.3, 1.4 \times 10^{11}$. The same convention for curves
holds for the insets.
effective masses make the second transition the dominant. This large difference in effective masses allows for gain even if there is considerably more global occupation in the lower subband.

Note that cross absorption in the high energy side of the stronger transition compensates the small gain without inversion for the weaker transition. Furthermore it is interesting to notice that the dispersive gain expected for LWI is found for similar effective masses. See Fig. 3(b) for the $e_{2+}$ to $e_{1-}$ transition, in which the upper and lower subband masses are given respectively by $m=0.125$ and 0.109. The dashed curve with equal densities in both subbands is the reference. In contrast, see the difference between the gain (around 600 meV) and the absorption regions (around 800 meV) in Fig. 3(c) for the $e_{2+}$ to $e_{3-}$ transition in which the lower and upper masses are given respectively by $m_{3+}=0.820$ and $m_{3+}=0.109$. The dispersive shape is strongly distorted. Again the dashed curve with the same global density of carriers in both subbands is the reference.

It should be pointed out that typical ISB relaxation times are generally short and that means that the pumping rate of the upper subbands should be large. Furthermore, the pumping mechanisms (carrier injection) do not populate the subbands homogeneously in general. Hence, at a very short time scale the populations around $k=0$ may be different from the thermalized distributions used here. Note however, that we have given the first step toward addressing those issues by considering more global carriers in the lower subbands and (not shown) by approximating strongly nonthermal distributions by a limiting worst case in which the upper subband have electrons thermalized at higher temperatures. We still found considerable gain for the same global densities and electronic temperatures 100 K higher in the upper subbands. Future work will use an extended version of our fully non-equilibrium approach that will start from the solutions of the Hamiltonian used here for each layer. In summary, this theoretical proof of concept shows that it is possible to engineer conduction subbands with substantial differences in effective masses which make gain without global inversion feasible in dilute nitride heterostructures. We find a strong link between the similarity of effective subband masses and dispersive gain features with contrasting results for very different masses. Our study suggests that designs based on the dilute nitride band engineering approach proposed here, with suitably smaller energy differences between the subbands leading to gain in the terahertz range and including the required depopulation channel, can deliver terahertz lasing at higher temperatures.
