Human schistosomiasis, caused by Schistosoma species, is a major public health problem affecting more than 700 million people in 78 countries, with over 40 mammalian host reservoir species complicating the transmission ecosystem. The primary cause of morbidity is considered to be granulomas induced by fertilized eggs of schistosomes in the liver and intestines. Some host species, like rats (Rattus norvegicus), are naturally intolerant to Schistosoma japonicum infection, and do not produce granulomas or pose a threat to transmission, while others, like mice and hamsters, are highly susceptible. The reasons behind these differences are still a mystery. Using inducible nitric oxide synthase knockout (iNOS−/−) Sprague-Dawley rats, we found that inherent high expression levels of iNOS in wild-type (WT) rats play an important role in blocking growth, reproductive organ formation, and egg development in S. japonicum, resulting in production of nonfertilized eggs. Granuloma formation, induced by fertilized eggs in the liver, was considerably exacerbated in the iNOS−/− rats compared with the WT rats. This inhibition by nitric oxide acts by affecting mitochondrial respiration and energy production in the parasite. Our work not only elucidates the innate mechanism that blocks the development and production of fertilized eggs in S. japonicum but also offers insights into a better understanding of host-parasite interactions and drug development strategies against schistosomiasis.

Schistosomiasis, caused by Schistosoma species, is the second most important parasitic disease for public health after malaria. In 2015, it was estimated that 700 million people were at the risk of this disease and 218 million people required treatment in 78 countries (1). Schistosoma japonicum is widely distributed in South China, Indonesia, and the Philippines (1), with 170,438 patients being treated in China in 2015 (2). It is well known that viable egg production is the key for both transmission and pathogenesis (egg-induced granulomas in the liver and intestinal tissues) of this parasite. The female S. japonicum produces around 3,000 eggs per day, 10-fold more than the related species Schistosoma mansoni, and this has been proposed to cause a more severe pathology to patients (3). S. japonicum is one of the most difficult parasites to control, because more than 46 nonhuman mammals can be naturally infected, especially cattle, goats, dogs, pigs, and mice, and these play an important role in the transmission of this disease in endemic regions (4, 5). However, it is well known that some experimental animals, such as Norway rats (Rattus norvegicus), show an innate resistance to infection, in which Schistosoma spp. cannot develop well and do not cause typical granuloma formation in the liver (6–8). These phenomena are described as susceptible or “permissive” and resistant or “nonpermissive” based on the capacity of the host species to allow development of sexual maturation and oviposition by the parasite (7). Although such natural characteristics have been investigated for several decades, little direct evidence has been obtained to fully explain these phenomena, even despite the publication of the genome of S. japonicum and the great benefits provided by it (9). We are interested to know why such huge differences in resistance occur between mice and rats when they are infected with S. japonicum.

What are the host factors that relate to innate resistance? Obviously, a better understanding of the mechanism of resistance would provide a better understanding of the pathogenesis of human schistosomiasis and the host–parasite interactions.

In recent decades, experiments have been carried out to investigate potential mechanisms that could mediate natural resistance to Schistosoma infection in rats. Capron and Capron (6) and Capron et al. (10), primarily using in vitro assays, argued that humoral immunity, particularly antibody-dependent, cell-mediated cytotoxicity, played a critical role in the resistance of the rat host. In addition, the anaphylactic antibodies (IgG2a and IgE) and effector cells, including eosinophils, macrophages, platelets, and mast cells, could mediate cytotoxicity, which might act directly against schistosomula in vivo (10, 11). However, some contrasting results have indicated that cell-mediated responses appeared to be insignificant in rat schistosomiasis (12). Moreover, some results also suggested that a Th2 type response was involved in such resistance, based on the observations of preferential expression of Th2 cytokines before rejection of worms.

Significance

Viable egg production by Schistosoma species is the key pathogenic process causing granuloma formation in permissive hosts (e.g., mice), while nonpermissive hosts [e.g., Norway rats (Rattus norvegicus)] avoid such sequelae. Using inducible nitric oxide synthase knockout (iNOS−/−) rats, we demonstrate that high expression levels of iNOS in rats play an important role in blocking the egg-induced granuloma formation of Schistosoma japonicum. The nitric oxide, produced by iNOS, inhibits parasite growth, reproductive organ development, egg production, and viability by interfering with mitochondrial function. This study solves the puzzle as to why rats are naturally resistant to S. japonicum infection and provides insights for understanding the pathogenesis of human schistosomiasis and the interactions between host and parasite.
in infected rats (12–14). Endocrine gland removal studies revealed that hormones from the pituitary and thyroid/parathyroid glands were required for innate resistance in rats (15), but no specific hormones were identified due to technical limitations at the time. Nevertheless, none of these proposed mechanisms could definitely and satisfactorily fully explain the resistance.

A comparison between mice and rats has clearly shown that the expression levels of inducible nitric oxide synthase (iNOS or NOS2) and the production of nitric oxide (NO) are barely detectable in naïve mice but significantly higher in naïve rats (16). This production of NO is typically dependent on L-arginine metabolism by iNOS in activated macrophages and other immune cells in response to microbial compounds and/or cytokines (e.g., IFN-γ, IL-1) (17, 18). NO has been identified as participating in macrophage-mediated killing or cyto-stasis of various extracellular or intracellular parasitic protozoans, such as Toxoplasma, Leishmania, Plasmodium, and Trypanosoma (17). In fact, some studies on NO have also been carried out on Schistosoma in a mouse model. For example, it was reported that macrophage and endothelial cell-mediated cytotoxicity against schistosomula of S. mansoni in vitro might be involved in the production of NO (19, 20). In addition, Wynn et al. (21) found that worm burdens were increased when mouse NO synthase activity was inhibited by aminoguanidine, a selective inhibitor of iNOS. Nevertheless, all of these studies were based on mouse models, and the role of NO in rats on infection by S. japonicum remains a mystery. We therefore hypothesized that the mechanism of natural resistance/intolerance to S. japonicum infection in rats could be related to inherent high expression levels of iNOS.

To test this hypothesis, iNOS knockout (iNOS−/−) Sprague-Dawley (SD) rats were used. We found that inherent high expression levels of iNOS in wild-type (WT) rats play a key role in blocking S. japonicum growth, reproductive organ development, egg production, and the ability to lay fertilized eggs. The consequences of this were to limit granuloma formation in the liver. We show that this inhibition by NO acts by affecting mitochondrial respiration and energy production in the worm. These findings not only provide direct evidence to demonstrate that NO is the key factor for natural resistance to S. japonicum infection in rats but also provide knowledge for a better understanding of the pathogenesis of schistosomiasis. They also inform potentially novel strategies to design new compounds and drugs to control schistosomiasis.

Results

NO Is a Key Molecule in Rats That Hampers the Development of S. japonicum. To test the hypothesis that NO plays an important role in the natural resistance/intolerance to S. japonicum infection in rats, initial studies were carried out to compare the status of NO production in BALB/c mice and SD and Lewis rats postinfection with S. japonicum. As expected, based on previous studies, development and fecundity levels of the parasite, parasite loads, and the size of granulomas in the tested animals were negatively correlated with their capacity to produce NO (Fig. S1), implying the inhibitory effect of NO in S. japonicum growth, maturation, fecundity, and pathogenesis.

Furthermore, iNOS−/− SD knockout rats were generated with undetectable NO production in peritoneal macrophages and lower levels of NO in sera (Fig. S2). Following infection, iNOS−/− rats showed a significant increase in worm burden (iNOS−/− rat, 82 ± 4; WT rat, 21 ± 2; P < 0.001) and egg deposition in the liver (eggs per gram of liver tissue: iNOS−/− rat, 106,334 ± 19,955; WT rat, 4,903 ± 1,239; P < 0.001; Table 1). Notably, the worm fecundity in the iNOS−/− rats, defined as the average egg production per female, was found to be nearly fivefold higher than that found in WT rats (Table 1).

To better understand the effects on S. japonicum in the iNOS−/− rat, detailed biological characteristics of the worms were examined. The lengths and diameters of male and female worms collected from iNOS−/− rats at 7 wk postinfection were significantly greater than those obtained from WT rats (Fig. 1A). The tegument of S. japonicum from the infected iNOS−/− rats was covered with well-arranged ridges and abundant pits, as well as sensory papillae with setae, and was similar to that of worms collected from mice (Fig. 1B and Fig. S3). However, in contrast, these characteristics were poorly developed in the worms from WT rats (Fig. 1B and Fig. S3). In addition, a large number of spines and several sensory papillae were found in the tegument of oral suckers of S. japonicum from iNOS−/− rats and mice but were not observed in the WT rat group (Fig. 1B).

Most importantly, we also found a huge difference between the reproductive systems of S. japonicum collected from iNOS−/− and WT rats. The testes of adult male schistosomes from iNOS−/− rats were composed of six to eight testicular lobes containing large amounts of spermatogonia and spermatocytes, while the seminal vesicle was filled with thousands of mature sperm (Fig. 1C). In the control mice, S. japonicum had a similar phenotype as in the iNOS−/− rats. In contrast, in WT rats, S. japonicum displayed a significant reduction in the number and size of testicular lobes, accompanied by a remarkable decrease in cell density in the testes plus a lack of mature sperm (Fig. 1C–E). Furthermore, in female worms, drastic differences were observed in the size of ovaries, vitellaria, and numbers of nonexcreted eggs in the uterus of S. japonicum collected from the iNOS−/− and WT rats (Fig. 1 C, F, and G and Fig. S4). Analogous to the worms observed in mice, we found that the ovaries of mature female worms collected from the iNOS−/− rats were composed of abundant oogonia, immature and primary oocytes (Fig. 1 C and F), while the uteri were filled with eggs (Fig. 1G and Fig. S4B) and the vitelline lobes were clustered with closely arranged vitelline cells (Fig. S4A). In contrast, there were significant reductions in the diameters of ovaries that contained only a few oocytes in the female worms collected from the WT rats (Fig. 1 C and F). The occurrence of eggs in uteri was rare, and those present were not properly formed; the vitelline lobes had scantily organized vitelline cells (Fig. 1G and Fig. S4). These results obtained from the WT rats are consistent with those previously described (8), but show a clear difference from phenotypes observed in the iNOS−/− rats.

WT and iNOS−/− rats were infected percutaneously with 200 cercariae of S. japonicum. Worm and egg burdens were determined at 7 wk postinfection. Data are expressed as the mean ± SEM (n = 10). Significant differences in characteristics were noted between WT and iNOS−/− rats. **P < 0.01; ***P < 0.001.

1The female worm numbers also indicate the numbers of pairs, as they were always found in pairs.
severe pulmonary granulomas were induced by eggs collected from the livers of iNOS\textsuperscript{−/−} rats than those from the WT rats, when injected i.v. into naïve mice (Fig. 2C and D).

To test the developmental status of S. japonicum eggs from the infected iNOS\textsuperscript{−/−} and WT rats, a hatching test was carried out. Parasite eggs recovered from the iNOS\textsuperscript{−/−} rats were capable of hatching to miracidia (25.3%) in a similar proportion to those recovered from mice (Fig. 2F). However, in contrast to the results from the iNOS\textsuperscript{−/−} rats, eggs collected from the WT rats were unable to hatch, thus demonstrating that NO has a specific role in affecting egg viability.

**Exacerbated Granuloma Formation in the iNOS\textsuperscript{−/−} Rats Was Attributed Only to the Full Development of Parasites, Not to Other Host Factors.** It is well known that viable eggs of schistosomes are a key factor for the formation of granulomas in their hosts (22). Indeed, as we predicted, rare and small granulomas were found in the liver of WT rats infected with S. japonicum at 7 and 12 wk postinfection, while both the number and size of granulomas were dramatically increased in the infected iNOS\textsuperscript{−/−} rats (Fig. 3A–C). The size of hepatic granulomas in iNOS\textsuperscript{−/−} rats infected with S. japonicum was 20.97 ± 1.87 (×10\textsuperscript{3} mm\textsuperscript{3}) at 7 wk postinfection, nearly eightfold larger than those found in the infected WT rats [2.56 ± 0.42 (×10\textsuperscript{3} mm\textsuperscript{3}); P < 0.001]. In a follow-up at 12 wk postinfection, the size of hepatic granulomas, remarkably, increased to 20.18 ± 25.91 (×10\textsuperscript{3} mm\textsuperscript{3}) in iNOS\textsuperscript{−/−} rats infected with S. japonicum, over 22-fold larger than those found in the infected WT rats [8.79 ± 0.83 (×10\textsuperscript{3} mm\textsuperscript{3}); P < 0.001; Fig. 3B]. Furthermore, comparison of the granuloma density of iNOS\textsuperscript{−/−} and WT rats showed an increase of 30-fold and 20-fold, respectively, in liver tissue in the knockout rats at 7 wk (WT: 0.09 ± 0.01%; iNOS\textsuperscript{−/−}: 2.73 ± 0.19%; P < 0.001) and 12 wk (WT: 0.43 ± 0.14%; iNOS\textsuperscript{−/−}: 8.84 ± 0.40%; P < 0.001) postinfection (Fig. 3C). The marked increase in hepatic granulomatous inflammation in the infected iNOS\textsuperscript{−/−} rats was largely dependent on the increased egg production of S. japonicum and maturation of eggs (Table 1 and Fig. 2F).

**S. japonicum Produced Viable Eggs in the Infected iNOS\textsuperscript{−/−} Rats.** To investigate the hypothesis that S. japonicum should produce nonfertilized eggs and underdeveloped embryos in the WT rats, acridine orange fluorescence staining was used as a detection system to measure viable egg production. We found a lower percentage (21.05%) of live eggs of S. japonicum from the WT rats, compared with a much higher percentage (86.28%) of viable eggs from the iNOS\textsuperscript{−/−} rats (Fig. 2A; P < 0.001). Furthermore, results from the circumoval precipitation reaction (CPR), a specific indicator of the secretion activity of viable mature eggs, showed that a characteristic and dense reaction product surrounded 29.58% of 2,000 eggs collected from the iNOS\textsuperscript{−/−} rats, while only weak CPR activity was observed in 5.42% of 1,200 eggs collected from the WT rats (Fig. 2B). Moreover, we found that much more
To exclude the possibility that the changes in host immunity factors post-NO deficiency may contribute to the hepatic granuloma, pulmonary granulomas were compared in the WT and iNOS−/− rats after injection of eggs obtained from rabbits infected with S. japonicum. To our surprise, similar sizes and volume density of pulmonary granulomas were observed in both the WT and iNOS−/− rats after injection of the same dose of viable mature eggs (Fig. S5). Thus, our results clearly demonstrated that the exacerbation of hepatic granulomas in the iNOS−/− rats was not attributed to host factors, but to the viability of Schistosoma eggs.

Adoptive Transfer of WT Macrophages into the iNOS−/− Rats Could Partially Restore the Inhibition Against S. japonicum. To provide further evidence of the role of NO in the inhibition of development of S. japonicum, adoptive transfer of WT rat macrophages (Mφ) into iNOS−/− rats was performed. Macrophages were used as they are considered to be the best-characterized source of NO (18). After transfer, the iNOS−/−/recipient rats (iNOS−/− + Mφ) that received adoptive transfer of WT macrophages were able to express iNOS (Fig. S6 A and B) and elevated the production of NO in vivo (Fig. S6 C). As seen in Table S1, in contrast to the status in the iNOS−/− rats, the worm burden and egg production, together with worm fecundity, were significantly reduced in the recipient group of animals (iNOS−/− + Mφ). Furthermore, we found that the adaptively transferred macrophages could partially inhibit the parasite growth, which resulted in a decrease in length and diameter (Fig. S6 D–F). As a consequence, the size of granulomas in live rats displayed a marked reduction in the iNOS−/− + Mφ group (Fig. S6 G and H). Thus, these data further demonstrated that NO is a key factor involved in blocking the development of S. japonicum in rats.

NO Inhibits the Mitochondrial Respiration of S. japonicum. In this study, we speculated that the mechanisms of NO blocking the development of Schistosoma might be linked to the inhibition of mitochondrial respiration, resulting in inhibition of mitochondrial energy production and lethal metabolic interference. To test this hypothesis, the mitochondrial morphology and structure of S. japonicum were compared. Ultrastructural observations revealed that worms from the mice had typical eukaryotic mitochondria with well-defined outer membranes and a clear cristae structure. In contrast, clusters of damaged mitochondria exhibiting mitochondrial swelling and distortion, loss of intact internal membranes, and disruption of mitochondrial cristae with vacuolization were observed in worms from the WT rats.

However, mitochondrial alterations were considerably diminished in the worms from the iNOS−/− rats (Fig. 4 A and Fig. S7). In addition, the relative mRNA expression of the mitochondrial respiratory chain enzymes, cytochrome c oxidase (CoO, complex IV) subunit I and NADH dehydrogenase (complex I), in worms from the WT rats was significantly decreased (Fig. S8). CoO activity was also significantly decreased in worms from the WT rats, compared with those from the iNOS−/− and mice (Fig. 4B). These results strongly suggest that the mechanisms of NO blocking the development of S. japonicum in rats act by affecting mitochondrial respiration in the parasite.

Discussion
Understanding defense mechanisms against parasites is a key aspect of elucidating host–parasite interactions. S. japonicum is a zoonotic parasite with a naturally wide permissive host range; however, some hosts, including the brown rat, are nonpermissive hosts. This provides a good model system for investigating the host–parasite interactions that control and limit infection. In permissive hosts, such as mice and hamsters, the parasites are able to reach sexual maturation and deposit eggs, which then trigger the formation of granulomas that are ultimately responsible for mortality. However, in nonpermissive hosts, such as rats, the parasites struggle to survive and do not fully develop into mature stages (7, 8, 15). Scientists have long been puzzled by these biological differences among mammalian species, and the causative mechanism(s) remained unclear; many hypotheses have been proposed to account for this (6, 12–14).

In early studies based on the mouse model, evidence indicated the effect of NO on killing Schistosoma (17), but the mechanism was not clarified. Based on our results from the rat models (WT vs. iNOS−/− and adoptive transfer of macrophages), we have demonstrated that high expression of iNOS with a higher amount of NO in rats is strongly linked to the inhibition of development of S. japonicum, and is a key factor contributing to their resistance against the parasite. The huge differences in development of S. japonicum between the WT and iNOS−/− rats clearly showed that NO could significantly influence the tegument structures, body size, and development of the reproductive organs in S. japonicum. The tegument is known to be required as essential protection for parasite survival during host immune attacks (23) and as a key structure for driving nutrient absorption and cholesterol metabolism (24, 25). The modified structure of the tegument of S. japonicum in WT rats causes significant problems for the absorption of nutrients and the development of the parasite. Importantly, we found that the reproductive organs of the female worms were not properly formed in the infected WT rats, represented as significant decreases in the size of ovaries and the number of vitelline cells and nonexcreted eggs compared with those found in iNOS−/− rats and mice groups. These deformities...
led to a significant decrease in both egg production and deposition in the tissues of the host. This, in turn, alleviated the pathogenesis caused by egg deposition. In fact, early evidence obtained from the mouse model system indicated similar effects of NO on S. mansoni when NO production was elevated by chemical compounds (26) or vaccination (27). Interestingly, the inhibition of development and fecundity by NO was also found in Cooperia oncophora, a parasitic nematode in cattle, in which elevated expression of iNOS was observed in acquired resistance during reinfestation of this parasite (28). Perhaps this represents a generic effect of NO in helminths. Alongside effects in females, we also found that NO could cause notable reductions in testicular lobe formation (both in size and quantity) and lack of production of mature sperm in the males of S. japonicum. In WT rats, the most significant effect of NO on the inhibition of S. japonicum was the production of nonfertilized eggs. This was manifested as a significant decrease in the proportion of viable eggs, showing a weak CPR and inability to lead to hatching of the important miracidial stages that are required for transmission to new hosts. Interestingly, removal of the pituitary gland and thyroid/parathyroid glands from rats before infection with S. mansoni resulted in increasing worm burdens, worm development, oviposition, and miracidial development (15). Indeed, growth hormone and thyroid hormones have been demonstrated to directly induce iNOS expression and increase iNOS activity by influencing the maturation and function of immune cells, such as macrophages (29–33). These results strongly support the important role of NO in the development of Schistosoma.

Egg granuloma formation in the liver and intestinal tissues of many permissive mammalian hosts, such as mice, has long been considered to be the primary cause of morbidity of schistosomiasis (34). This is reported to be caused by antigens secreted by the mature viable eggs (22), followed by induction of inflammatory cells surrounding the eggs (34). In fact, rare egg granulomas have also reportedly been found in nonpermissive hosts (7, 8). In our work, we found that S. japonicum worms developing in WT rats laid 20-fold fewer eggs than those developing in the iNOS−/− rats. Surprisingly, the magnitude of change in egg granuloma production (volume density) between WT and iNOS−/− rats was more than 30-fold. This clearly indicated that the viability of eggs contributed to the difference observed. This result is consistent with the observation that eggs of Schistosoma are able to induce egg granuloma formation in their hosts (22). However, it was still unclear in previous studies why such obvious differences occur between permissive and nonpermissive hosts during infection with S. japonicum. This was largely attributed to host specificity, although detailed mechanisms were not then forthcoming.

There was some evidence suggesting that NO could play a direct role in limiting granulomatous inflammation in iNOS−/− mice infected with S. mansoni (35) and in the in vitro granuloma reaction with the iNOS inhibitor Nω-nitro-ω-arginine methyl ester (Nω-NAME) (36). However, this inhibition effect was not observed when aminoguanidine was administered to mice infected with S. mansoni (37), and it was not observed when the inhibitors l-Nα-(uninoenethyl)-lysine and l-NAME were used in a model where hepatic granulomas were induced by implanting S. japonicum eggs (38); however, the toxicity of these inhibitors to the parasites had not been clarified. In our study, we were able to exclude the effect of host immunity factors, post-NO deficiency, on egg granuloma formation and attribute it solely to the quantity and viability of parasite eggs. This was confirmed by observing a similar volume density and size of pulmonary granulomas formed in both the WT and iNOS−/− rats following injection with the same dose of viable mature eggs.

NO is an unusual effector molecule because of its ability to diffuse freely across cell membranes. This allows it to diffuse into the worm (39) and to directly influence its physiology (e.g., toxic peroxynitrite anion) (17, 40) or to indirectly (e.g., via S-nitrosylation) target inactivation and degradation of iron-containing enzymes (17, 40, 41), which were essential for parasite metabolism (42, 43). For example, earlier studies suggested that NO/nitrite could mediate in vitro schistosomula killing by causing mitochondrial lesions and inhibition of mitochondrial respiration (19, 44). In fact, mitochondrial metabolism, especially the tricarboxylic acid cycle, has been shown to have an essential function in S. japonicum (45). This was demonstrated by using fluoroacetate, an inhibitor of aconitate, and showing that it could cause a separation and hepatic shift of paired worms; a significant fall in both glycogen and protein content; and consequently, a considerable loss of worm body weight. Other studies demonstrated that the mitochondrial respiratory chain also plays an important role in egg production (45) and biosynthetic processes in Schistosoma (46), which are important in rebuilding the surface membrane complex to protect schistosomes from immune attack (23, 46). In addition to the detailed knowledge in Schistosoma, mitochondrial respiration is known to be required for development in other parasitic nematodes (47), suggesting a general role in helminth survival and transmission. Our data clearly show damaged mitochondria in the surviving S. japonicum worms collected from infected WT rats, while observing typical normal mitochondrial structures in the worms collected from the iNOS−/− rats infected with the same parasite. Respiration chain impairment was confirmed by significant decreases in expression levels of complexes I and IV (CoQ) and CoQ activity, which usually is responsible for 90% of oxygen consumption (48, 49). A large number of pioneering studies have documented that NO can inhibit CoQ in competition with oxygen (48, 50, 51). Such suppression of CoQ activity is reversible (48, 52). In fact, a parasite transfer study that was carried out in rats showed results consistent with this notion of reversible inhibition of the development and fecundity of Schistosoma (7). By analysis of the function of mitochondrial of S. japonicum collected from the WT and iNOS−/− rats, our results strongly suggest that the mechanisms of NO blocking of the development of S. japonicum in rats act by affecting the mitochondrial respiration.

Taken together, our results demonstrate unequivocally that the key role of NO in blocking the development of S. japonicum may be strongly linked to the inhibition of parasite mitochondrial respiration, which, in turn, leads to decreases in worm survival, egg production, and quantity of fertilized eggs. This consequently limits granuloma formation in the liver and subsequent pathogenesis. By studying the reproductive biology of schistosomes in this way, our results not only solve the long-term puzzle as to why rats are naturally resistant/intolerant to S. japonicum infection but also offer insights into possible control. The knowledge that the interaction and evolution of host and parasite are functionally driven by host NO production suggests new strategies for the design of new compounds and drugs for the control and prevention of human schistosomiasis. We also propose that this iNOS−/− rat model will be a highly beneficial and generic model for determining the role of NO in resistance/intolerance to other pathogen infections.

**Materials and Methods**

**Animals.** Six- to eight-week-old male Bagg albino (BALB/c) mice and SD rats were purchased from the Laboratory Animal Center of Sun Yat-Sen University. Six- to eight-week-old male Lewis rats were purchased from Vital River Laboratories. The iNOS-deficient rats were generated by transcripion activator-like effector nucleases (TALENs) technology and breeding at the specific-pathogen-free (SPF) house of Sun Yat-Sen University. The mutant rats are viable and fertile, and do not display any obvious appearance or physical abnormalities. All animals were housed under specific pathogen-free conditions, and this work was approved by the Laboratory Animal Use and Care Committee of Sun Yat-Sen University under license no. 2012CB53000.

**Parasite infection.** Cercariae of S. japonicum (Chinese mainland strain) were obtained from infected Oncomelania hupensis snails purchased from the
We thank the members of our laboratories, who provided great help during the work. This work was supported by the National Key R&D Program of China (2016YFC1200500) and National Science Foundation of China (Grants 31472058, 31402029, 31672276, and 81527024).

ACKNOWLEDGMENTS. We thank the members of our laboratories, who provided great help during the work. This work was supported by the National Key R&D Program of China (2016YFC1200500) and National Science Foundation of China (Grants 31472058, 31402029, 31672276, and 81527024).
